Ipa013. Fish-scale die migration dynamics of an island-associated sound-scattering layer. Kelly Banfield-Brad and Whitlow Aw (Hawaii Inst of Marine Biol., P.O. Box 1106, Kailua, HI 96734)

The Hawaiian mesopelagic boundary community, an island-associated midwater sound-scattering layer, undergoes fish-scale vertical and horizontal migrations. To understand the dynamics of the community’s migration at small temporal scales and large spatial scales, five bottom-mounted, 200-kHz active-acoustic mooring that transmitted ten signals every 15 min, from dusk until dawn for 5 days. Two layers within the boundary community were observed to undergo simultaneous fish-scale vertical and horizontal migration. Vertical migration rates were measured at 0–17 m/min, while the horizontal rate averaged 1.67 km/hr, swamping the vertical movement. The vertices of the migration pattern was observed 45 min before the mid-point between sunset and sunrise. Until the vertices, animal density increased relatively constantly as the animals migrated towards shore. With the highest animal densities found in the shallowest areas at midnight. Animal abundance estimates at the leading and trailing edge of the layer support the hypothesis that increased animal densities near shore are related to packing, as mesopelagic animals avoid the surface and the bottom. We observed high levels of biomass moving rapidly, over a great distance, into shallow waters very close to shore, providing insight into the significant link the mesopelagic boundary community provides between nearshore and oceanic systems.

Ipa014. Tidal matched field processing inversion for water depth and source range in the Ionian96 test. A. Tolstoy (A&Tolstoy Sc., 8610 Breliaies Court, Annandale, VA 22003, atolstoy@ieee.org), S. Jesus, and O. Rodriguez (Univ. of Algarve, Faro, Portugal)

Examining Ionian96 hydrophone data (300 to 800 Hz) we see clearly the effects of tidal changes, i.e., of changing water depths. In this work we will examine Matched Field Processing (MFP) sensitivity at that range of frequencies to expected tidal changes (the depth varies ±1.0 m from the nominal of 135 m). Is it possible to invert such data to accurately and uniquely estimate water depth D as a function of time (tides)? What about accurate, unique, simultaneous estimates of source range r? What happens when we use multiple frequencies and when D is known to shift in a predictable fashion? Can the r vs D ambiguity ever be resolved for a successful, unique MFP inversion for those parameters?

Ipa015. Influence of fetch limited surface roughness on mid-to-high frequency acoustic propagation in shallow water. Robert Heitsenrether, Mohsen Radley (Ocean Acoust. Lab., College of Marine Studies, Univ. of Delaware, Newark, DE 19716, rhet@udel.edu), James Kirby (Ct. for Appl. Coastal Res., Univ. of Delaware, Newark, DE 19716), and Steve Fosythe (Naval Undersea Warfare Ctr., Newport, RI 02843)

Surface waves are among several environmental parameters that can influence mid-to-high frequency (1–18 kHz) acoustic wave propagation. Understanding the interaction of sound waves at a rough surface requires a detailed description of the wave spectrum. In shallow water regions, due to proximity to land, surface waves are usually fetch and duration limited with reduced spectral level and higher frequency components. A model that approximates the wave spectra for a fetch limited sea has been combined with acoustic ray-based method for analysis of forward scattered acoustic signals in such a coastal environment. Numerical modeling is employed to investigate time-frequency-attenuation characteristics of ray paths reflected from a rough sea surface. Temporal variability of acoustic signal fluctuations has been examined as a function of varying sea surface. To validate this model, results are compared against a unique set of experimental data collected in a fetch limited region. The experimental design allowed an examination of time evolution of a single surface bounced ray path. Simultaneous wind speed and acoustic propagation measurements allowed correlation between the individual ray paths and the sea surface at varying sea state conditions. For low wind speed conditions, model results predict the temporal fluctuations of the measured acoustic signal propagation.

Session IpbB

Biomedical Ultrasound/Bioresponse to Vibration and Signal Processing in Acoustics: Acoustic Microscopy

Joie P. Jones, Chair

Radiological Sciences, University of California, Irvine, California 92697-5000

Invited Papers

1:00

IpbB1. A short history of the development of acoustic microscopy. Joie Jones (Dept. of Radiol, Univ. of California, Irvine, Irvine, CA 92697-5000, jjjones@uci.edu)

Optical microscopy has a long and interesting history, going back thousands of years to discoveries made in both Assyrian and Mayan cultures. Acoustical microscopy, on the other hand, has had a much shorter but equally interesting history, going back only to the mid-20th century. This presentation traces the development of acoustic microscopy from its very beginnings to the present. Comparisons with other microscopic techniques will point out the unique features offered by acoustical microscopy. A wide range of application areas will be reviewed and future prospects and potentials discussed.
